***Abstract*—Autonomous robots require robust path planning algorithms to navigate complex environments efficiently. This study compares A*, Breadth-First Search (BFS), and Depth-First Search (DFS) for optimal path planning in diverse scenarios. Using a 10x10 grid with static and dynamic obstacles, we assess these algorithms based on computation time, path length, memory usage, success rate, and adaptability to dynamic conditions. A* employs heuristic optimization for balanced performance, BFS guarantees shortest paths in uniform grids, and DFS prioritizes deep exploration for specific use cases. Results show A* achieves 78.5% path optimality with a 94.2% success rate, BFS ensures 100% optimality but with higher memory demands, and DFS offers rapid execution (28.4 ms) but only 65.4% optimality. These findings provide practical insights for algorithm selection in real-time robotic applications, with A* being optimal for dynamic environments, while BFS and DFS excel in specific structured settings.**

I. Introduction

Autonomous robots rely on efficient path planning algorithms to navigate complex environments while avoiding obstacles [1], [14]. As robotic applications expand in fields like industrial automation, autonomous vehicles, and service robotics, advanced navigation systems are critical for computing optimal paths under diverse constraints [2], [15]. Algorithms such as A*, Breadth-First Search (BFS), and Depth-First Search (DFS) are foundational in addressing these challenges [3], [12]. This study provides a comparative analysis to guide algorithm selection for real-world robotic navigation [17].

These algorithms find applications in robotic navigation, video games, and AI planning systems [4], [16]. Understanding their strengths and limitations is essential for selecting the appropriate method for specific environments [5]. With the

rapid growth of autonomous systems, efficient path planning remains a pivotal research area [6].

This paper investigates the operational principles of A*, BFS, and DFS, evaluating their performance in terms of computation time, path optimality, memory efficiency, and adaptability to dynamic obstacles [7], [9]. It addresses practical challenges such as sensor uncertainty and computational constraints [10], offering insights for real-time robotic applications.

II. Background and Literature Review

Path planning algorithms are central to robotics and artificial intelligence. Hart et al. [1] introduced A*, leveraging heuristics to balance accuracy and efficiency, establishing it as a benchmark for informed search algorithms. Cormen et al. [2] provided rigorous analyses of BFS and DFS, proving their completeness and optimality in specific graph scenarios. Dijkstra's work on graph traversal [3] laid the foundation for modern path planning, while Latombe [14] formalized path planning for robotic systems.

Doe et al. [4] enhanced A* with dynamic weighting, achieving a 30% reduction in execution time while preserving path quality. Kapoor et al. [6] demonstrated BFS's reliability in uniform-cost grid navigation, though it incurs high memory costs. Liu and Zhang [7] explored DFS for maze-like environments, noting its memory efficiency despite suboptimal paths. Mehta [8] compared multiple algorithms, concluding that performance varies by scenario. Johnson and Williams [9] proposed hybrid approaches to combine algorithm strengths, while Choset et al. [15] provided a comprehensive framework for robotic motion planning. Probabilistic methods, such as those by Kavraki et al. [16], offer alternatives for complex environments, and LaValle [13] extended planning algorithms to dynamic settings.

Research gaps include limited studies on dynamic obstacle avoidance, trade-offs between computational efficiency and path optimality, and real-world challenges like sensor uncertainty [10]. Recent work by Chen and Li [11] leverages parallel computing to reduce A*'s time complexity, enabling real-time path planning [12], [18].

III. Materials and Methods

We conducted experiments in a simulated 10x10 grid environment with static and dynamic obstacles. The dataset comprises 50 unique grid configurations, each with varying start and goal points and obstacle placements, yielding 500 rows (50 configurations × 10 rows) and 10 columns per grid.

Pre-processing steps include:

- Grid normalization: Cell values scaled to 0 (free) or 1 (obstacle).
- Obstacle encoding: Static obstacles (value 1); dynamic obstacles (values 0.5–0.9 based on movement probability).
- Path traversability: Calculated as the inverse of obstacle value.
- Data augmentation: Applied rotation and mirroring to generate additional test cases.

The algorithms were implemented in Python 3.8 using NumPy 1.19.5 and executed on an Intel i7-10700 (2.9 GHz, 8 cores) with 16 GB RAM, running Ubuntu 20.04 LTS. Performance metrics included:

- Execution time (ms)
- Path length (steps)
- Memory consumption (KB)
- Success rate (%)
- Path optimality (ratio to theoretical minimum)

Each algorithm was tested 100 times per configuration to ensure statistical significance [8].

IV. Methodology

A. A* Algorithm

A* employs a heuristic function to guide search, combining the cost from the start node ($g(n)$) and the estimated cost to the goal ($h(n)$), as shown in Eq. IV-A:

$$f(n) = g(n) + h(n)$$

Here, $g(n)$ represents the exact cost from the start to node n, and $h(n)$ is the estimated cost to the goal, ensuring efficient exploration in grid-based environments

$$h(n) = |x_n - x_{goal}| + |y_n - y_{goal}|$$

A* maintains an open list of nodes to explore and a closed list of visited nodes [1]. This approach balances optimality and speed, making it ideal for real-time robotic navigation

Algorithm 1 A* Path Planning Algorithm

```
Initialize open list with start node, closed list as empty
Set g(start) = 0, f(start) = h(start)
while open list is not empty do
    Select node n with lowest f(n)
    if n is goal then
        Reconstruct and return path
    end if
    Move n from open to closed list
    for each neighbor m of n do
        if m not in closed list then
            Compute tentative g(m) = g(n) + cost(n, m)
            if m not in open list or tentative g(m) < g(m) then
                Update g(m), f(m) = g(m) + h(m)
                Set m's parent to n
                Add m to open list if not already present
            end if
        end if
    end for
end while
Return failure if goal not reached
```

B. BFS Algorithm

BFS explores nodes level by level using a queue, ensuring the shortest path in unweighted graphs [2]. It is memory-intensive due to storing all nodes at the current level, with a space complexity of $O(b^d)$, where b is the branching factor and d is the solution depth

C. DFS Algorithm

DFS explores paths deeply using a stack, with a space complexity of $O(b \cdot d)$ [3]. It is memory-efficient but may produce suboptimal paths, making it suitable for memory-constrained systems or maze-like environments

V. Results

Table I compares A*, BFS, and DFS across key metrics. A* offers balanced performance, BFS ensures optimal paths at high memory cost, and DFS is fastest but least optimal.[1]

TABLE I
Performance Comparison of Path Planning Algorithms

Algorithm	Avg. Time (ms)	Memory (KB)	Optimality (%)
A*	45.3	1245	78.5
BFS	82.7	3876	100.0
DFS	28.4	683	65.4

Table II presents time complexity and measured execution times for different grid sizes, including a 20x20 grid to evaluate scalability.

TABLE II
Time Complexity Analysis for Different Grid Sizes

Algorithm	Theoretical	10x10 Grid (ms)	20x20 Grid (ms)
A*	$O(b^d)$	45.3	162.7
BFS	$O(b^d)$	82.7	298.4
DFS	$O(b \cdot d)$	28.4	94.6

Table III shows performance across varying obstacle densities, including average path length.

TABLE III
Algorithm Performance with Different Obstacle Densities

Obs. Density	A* Succ. (%)	BFS Succ. (%)	DFS Succ. (%)
Low (10%)	99.8	98.5	94.6
Medium (30%)	96.3	91.2	78.9
High (50%)	86.5	79.0	43.5

Table IV evaluates algorithm adaptability in dynamic environments with moving obstacles, highlighting A*'s superior performance [18].

Figures 2–7 visualize the optimal and explored paths for A*, BFS, and DFS on a map of Manipal Institute of Technology (MAHE). The implementation allows selecting random start and goal points, with A* demonstrating the most efficient exploration.

[1]Success rate is calculated as the percentage of configurations where the algorithm reaches the goal within 1000 steps.

TABLE IV
Performance in Dynamic Environments (10x10 Grid)

Algorithm	Replan Time (ms)	Success Rate (%)	Path Length (steps)
A*	48.7	92.1	14.2
BFS	89.3	87.6	13.8
DFS	32.1	68.4	17.5

VI. Discussion

A* achieves a success rate of 94.2% and 78.5% path optimality, making it ideal for real-time navigation due to its balanced efficiency and adaptability [5], [13]. BFS, with 100% optimality but higher memory usage (3876 KB) and slower execution (82.7 ms), suits static environments where path quality is paramount

Our results align with Doe et al. [4], who reported A*'s efficiency in dynamic settings, and Mehta [8], who noted scenario-specific algorithm strengths. Table IV shows A*'s superior adaptability in dynamic environments, with a replan time of 48.7 ms and a 92.1% success rate

A prototype hybrid A*-BFS approach, combining A*'s heuristic efficiency with BFS's optimality, was tested on five 10x10 grid configurations, yielding a 90.5% success rate and 95.2% optimality, suggesting potential for future work [9],

Challenges include scaling to larger dynamic maps, integrating real-time updates, and handling sensor uncertainty [10]. Future work should explore hybrid algorithms that adaptively switch strategies based on environmental conditions and leverage parallel computing for real-time performance

VII. Conclusion

This study compared A*, BFS, and DFS for autonomous robot navigation in a 10x10 grid, providing practical insights for algorithm selection. A* offers a robust solution for real-time applications, BFS ensures optimal paths in static grids, and DFS suits memory-constrained scenarios. These findings guide the design of navigation systems for diverse robotic applications [14],
